

## Millimeter-wave High-Efficiency Multilayer Parasitic Microstrip Antenna Array for System-on-package

*Tomohiro Seki, Kenjiro Nishikawa<sup>†</sup>, Ichihiko Toyoda, and Koichi Tsunekawa*

### Abstract

This paper describes the design and characteristics of a highly efficient multilayer parasitic microstrip antenna array (MPMAA) constructed on a multilayer substrate for millimeter-wave system-on-package modules. The antenna on a Teflon substrate achieved a radiation efficiency of greater than 91% and an associated antenna gain of 11.1 dBi at 60 GHz. Its size is only 10 mm × 10 mm. We discuss MPMAAs fabricated on both Teflon and low-temperature cofired ceramic (LTCC) substrates. The measured performances of prototype antennas are also presented. The MPMAA offers compactness and high efficiency and is easily integrated with the system-on-package design. It will lead to compact and cost-effective millimeter-wave RF modules.

### 1. Introduction

The strong demand for high-speed wireless applications has stimulated the development of millimeter-wave and quasi-millimeter-wave wireless equipment [1]-[3]. V-band (50–75 GHz) wireless systems are very interesting because they offer much higher transmission rates, above 1 Gbit/s, due to their wider bandwidths. These applications require compact, high-performance, and cost-effective wireless equipment. A highly integrated RF (radio frequency) module, known as a system-on-package module, which has a multilayer structure, is effective in meeting these requirements [4]-[7]. It is necessary to use active integrated antenna technology to make a module integrated with antennas that consume little power and have low-noise characteristics [8]-[10].

Several approaches to achieve an RF module integrated with antennas have been reported.

1) One approach is a semiconductor on-chip antenna such as a microstrip antenna (MSA) that is integrated with RF circuits on the same semiconductor substrate [4]. However, in this approach it is difficult

to establish a high-gain antenna having an antenna array configuration on a semiconductor substrate due to the substrate's size and loss. Therefore, high-gain compact antennas have not yet been integrated with monolithic microwave integrated circuits (MMICs).

2) A multi-chip module approach has also been proposed for a module integrated with antennas [5], [6]. In this module, antennas and MMICs are connected by wire bonding or a ribbon, which results in a high connection loss. This approach also requires a low-loss feeding circuit.

3) A dielectric lens antenna has been used to achieve a high-gain antenna [7]. However, the commonly used lens antenna is constructed using an expensive crystal material and it is difficult to mount it on the MMIC package. Thus, a dielectric lens antenna fabricated using resin was investigated as a low cost alternative.

There are problems, however, in mounting the antenna on the MMIC package and achieving high efficiency. Moreover, it is difficult to construct an antenna array substrate on a single layer due to the limitations of the manufacturing process for the millimeter-wave frequency band.

A technique for improving the radiation efficiency by arranging parasitic elements above the feeding microstrip antenna elements has been investigated

<sup>†</sup> NTT Network Innovation Laboratories

E-mail: nisikawa.kenjiro@lab.ntt.co.jp

[11]-[15]. However, obtaining a sufficient absolute gain was difficult in these studies [11]-[14]. A high gain antenna using a low-permittivity layer or an air layer has been investigated, but only the directional gain was described and it was difficult to use this antenna in a system-on-package design due to the parasitic element substrates.

To overcome the above problems, we are studying a multilayer parasitic microstrip antenna array (MPMAA) structure based on a parasitic antenna configuration [16], [17]. This paper describes a highly efficient MPMAA structure for a system-on-package module at millimeter-wave frequency bands. At 60 GHz, the antenna on a Teflon substrate achieves high radiation efficiency of greater than 91% and high gain of greater than 11.1 dBi. The rest of this paper is organized as follows. Section 2 describe the concept of the system-on-package module and the design of the antenna. Section 3 presents the effect of the alignment precision of the manufacturing process. Finally, Section 4 presents measurement results for prototype 60-GHz band antennas fabricated on Teflon and low-temperature cofired ceramic (LTCC)\* substrates. Our MPMAA offers compactness and high-efficiency performance for millimeter-wave system-on-package modules.

## 2. Design of parasitic element arrangement on Teflon substrate

### 2.1 Concept of millimeter-wave system-on-package

The concept of a system-on-package module integrated with an antenna is shown in Fig. 1. An MPMAA and a highly integrated transceiver MMIC are mounted on a multilayer structure, in a vertical stacking configuration. Two types of feeding methods for the MPMAA are considered. In the first method, a feeding element is constructed on the MMIC chip, and the MPMAA is fed by electromagnetic coupling without a feeding line. In the other, a feeding element is constructed where the multilayer substrate of the MPMAA and the element are connected to the terminal of the MMIC using flip-chip technology. As indicated in Fig. 1, the MPMAA uses two parasitic layers with four parasitic elements on each layer.

### 2.2 MPMAA design

This antenna achieves high gain because it increases the antenna aperture by utilizing the coupling

between the layers of the multilayer substrate. Here, we describe the MPMAA design for the 60-GHz band. We use the moment method as the calculation method and assume that the ground plane is infinite. To clarify the MPMAA's characteristics, we use a multilayer Teflon substrate ( $\epsilon_r = 2.2$ ,  $\tan\delta = 0.0007$  at 10 GHz) as the antenna substrate. The MPMAA on the Teflon substrate also exhibits excellent characteristics such as a high gain and a wide bandwidth. A simulation model for the MPMAA is shown in Fig. 2. Here, we use the via-fed method for the feeding method. The size of the feeding element is  $0.30 \lambda_0 \times 0.30 \lambda_0$  and the feeding point is  $0.01 \lambda_0$  away from the center of the patch, where  $\lambda_0$  is the free-space wavelength. The size of the parasitic elements mounted on the first parasitic layer is  $0.32 \lambda_0 \times 0.32 \lambda_0$  and the patch size of the second parasitic layer is  $0.28 \lambda_0 \times 0.28 \lambda_0$ . The four parasitic elements mounted on the

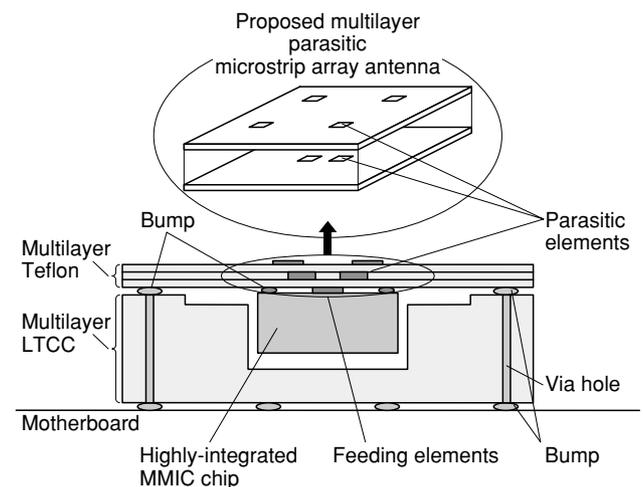

Fig. 1. Novel structure of system-on-package integrated with antenna.

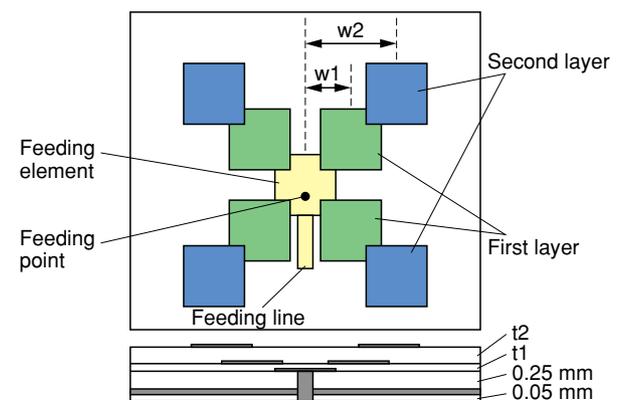

Fig. 2. Antenna model.

\* LTCC is a glass ceramics to be fired at around 900°C.

first parasitic layer are arranged so that they are equidistant from the center of the feeding MSA. For convenience, the width (horizontal direction) is expressed so that the widths of the first and second parasitic layers are  $w_1$  and  $w_2$ , respectively. In addition,  $t_1$  and  $t_2$  represent the substrate thicknesses of the first and second parasitic layers, respectively. The relationship between  $w_1$  and  $w_2$  that yields the maximum absolute gain is shown in **Fig. 3**. Here,  $t_1$  and  $t_2$  were set to 0.25 and 0.55 mm, respectively. In this figure, it is clear that  $w_1$  is proportional to  $w_2$ . The relationships between maximum absolute gain and  $w_2$  and between radiation efficiency and  $w_2$  are shown in **Fig. 4**. Here, the substrate thickness parameters were the same. In this figure, it is clear that the maximum absolute gain is 11.1 dBi and that the radiation efficiency is 91% when  $w_1$  is  $0.22 \lambda_0$  and  $w_2$  is  $0.28 \lambda_0$ . The antenna achieves the maximum radiation efficiency of 97% when  $w_2$  is  $0.32 \lambda_0$ . We

believe that, in this case, the peak of the absolute gain is obtained by increasing the antenna aperture as the number of parasitic elements increases and the efficiency degrades due to the decrease in the coupling between the feed element and the parasitic elements. Additionally, it is necessary to clarify the effect of substrate thickness on the parasitic elements. The dependence of the absolute gain on the substrate thicknesses,  $t_1$  and  $t_2$ , is shown in **Fig. 5**. When  $t_1$  and  $t_2$  are 0.25 and 0.55 mm, respectively, the absolute gain has the maximum value of 11.1 dBi. Additionally, it is clear that the manufacturing margins of  $t_1$  and  $t_2$  are approximately 150 and 100  $\mu\text{m}$ , respectively, and the gain reduction is less than 0.5 dB. Furthermore, it is clear that the precision of the substrate thickness of the conventional multilayer Teflon substrate process is sufficient to construct this proposed antenna. The antenna's frequency characteristics (**Fig. 6**) show that the bandwidth is 2.6% when the  $S_{11}$

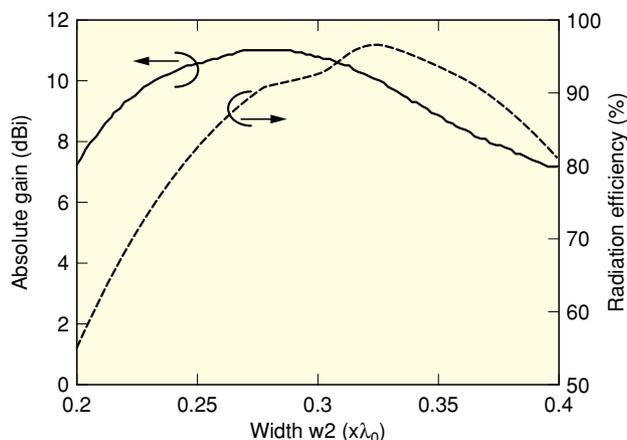

Fig. 4. Absolute gain and radiation efficiency characteristics versus  $w_2$ .

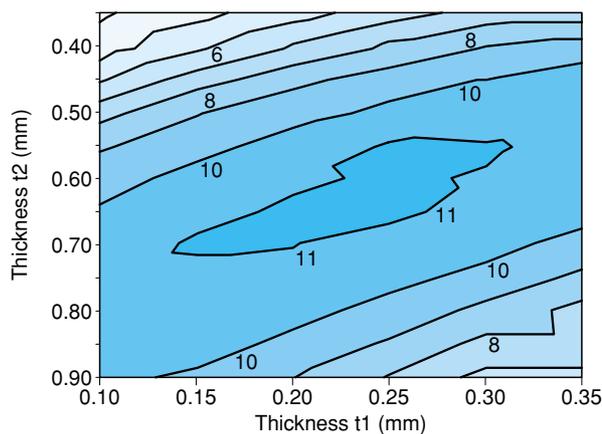

Fig. 5. Absolute gain characteristics versus substrate thicknesses  $t_1$  and  $t_2$ .

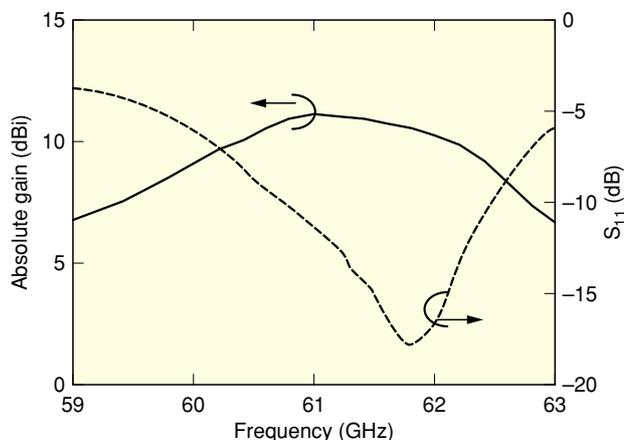

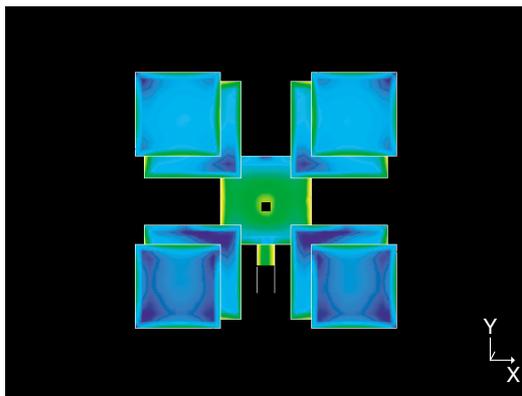

Fig. 6. Calculated frequency characteristics of the absolute gain and  $S_{11}$ .

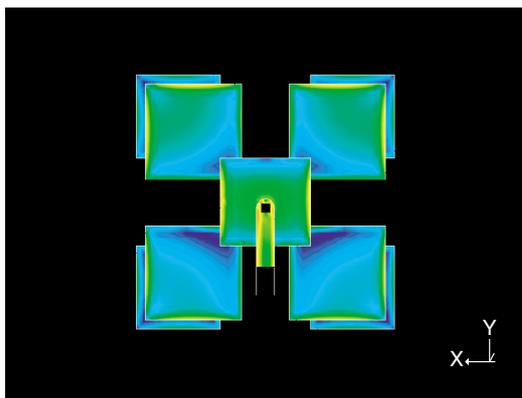

characteristics are less than  $-10$  dB. To consider the mechanism of this antenna, we calculated the current distribution using the moment method analysis. The results in Fig. 7 show that in the feeding element, the current is distributed to the first layer parasitic elements and via them to the second-layer parasitic elements. The RF signal can be effectively separated from the feeding element and passed to the second-layer parasitic elements without using a power divider circuit, so array operation can be achieved.

### 2.3 Effect of the substrate on MPMAA

To make the system-on-package module, we investigated several substrates. In this section, we describe the dependence of the antenna's performance on the key substrate characteristic: the effective dielectric constant. Figure 8 shows the positions of the parasitic elements that give maximum antenna gain as a function of the effective dielectric constant of a sub-

(a) Front view

(b) Rear view

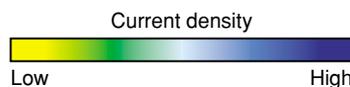

Fig. 7. Current distribution of the proposed antenna.

strate. The corresponding maximum antenna gain is plotted in Fig. 9. As the effective dielectric constant of the substrate increased,  $w_1$  and  $w_2$  decreased. They saturated when the effective dielectric constant was more than 7.5. On the other hand, the corresponding maximum gain continuously decreased. However, the MPMAA fabricated on an LTCC substrate ( $\epsilon_r = 7.7$ ,  $\tan\delta = 0.002$  at 10 GHz) achieved antenna gain of more than 8 dBi. These results indicate that our MPMAA can offer reasonable antenna gain even if we use low-cost materials, such as LTCC or high-temperature cofired ceramic (HTCC), for the substrate.

### 3. Effect of alignment precision

The antenna constructed on a multilayered Teflon substrate that binds the substrates using a bonding

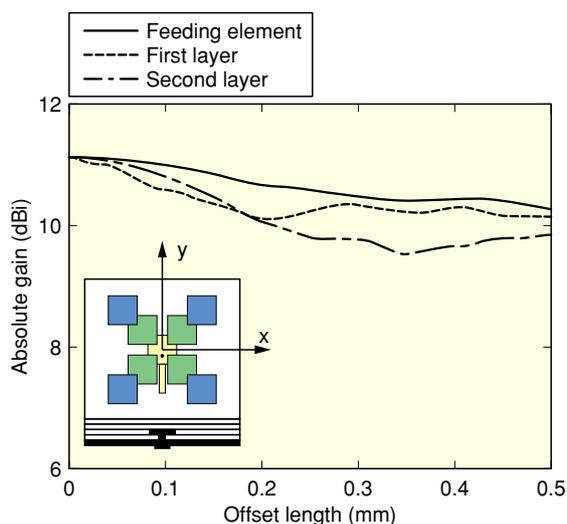

Fig. 10. Absolute gain reduction versus alignment precision of x-axis direction.

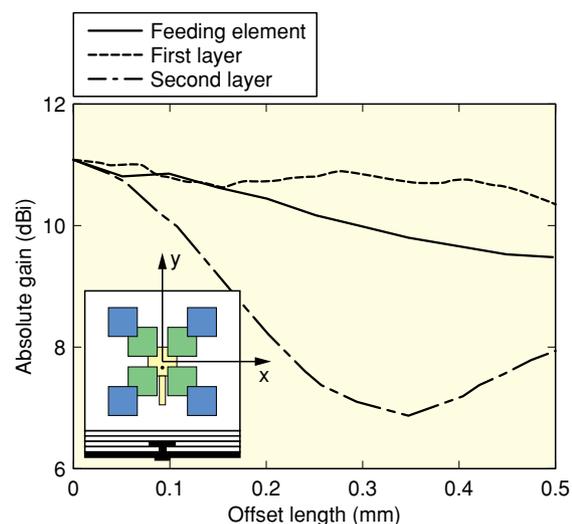

Fig. 11. Absolute gain reduction versus alignment precision of y-axis direction.

film is more sensitive to alignment precision than antennas on other substrates such as an alumina-ceramic substrate. Therefore, we need to clarify the effect of alignment error due to the binding substrates. We used the moment method for the calculation. The size of the feeding element was  $0.30 \lambda_0 \times 0.30 \lambda_0$  and the feeding point was  $0.01 \lambda_0$  away from the center of the patch. The size of the parasitic elements mounted on the first parasitic layer was  $0.32 \lambda_0 \times 0.32 \lambda_0$  and the patch size of the second parasitic layer was  $0.28 \lambda_0 \times 0.28 \lambda_0$ . Furthermore, the position of the first parasitic layer was  $x: \pm 0.22 \lambda_0, y: \pm 0.22 \lambda_0$  and the position of the second parasitic layer was  $x: \pm 0.28 \lambda_0, y: \pm 0.28 \lambda_0$ . The calculated absolute gain reductions when alignment errors occur in the direction of the x- and y-axes are shown in **Figs. 10** and **11**, respectively. Alignment errors in the y-axis direction clearly had a greater effect than those in the x-axis direction. We believe this is because there was a standing wave in the direction of the y-axis of each patch. Moreover, it is clear that the alignment margins of the first-and second-layer parasitic substrate are approximately  $\pm 100$  and  $\pm 50$   $\mu\text{m}$ , respectively, and that the gain reduction is less than 0.5 dB. Furthermore, the simulation results indicate that the alignment precision of the conventional multilayer Teflon substrate process is sufficient to construct this antenna.

## 4. Measured performance

### 4.1 Measurement system

In the millimeter-wave frequency range, one impor-

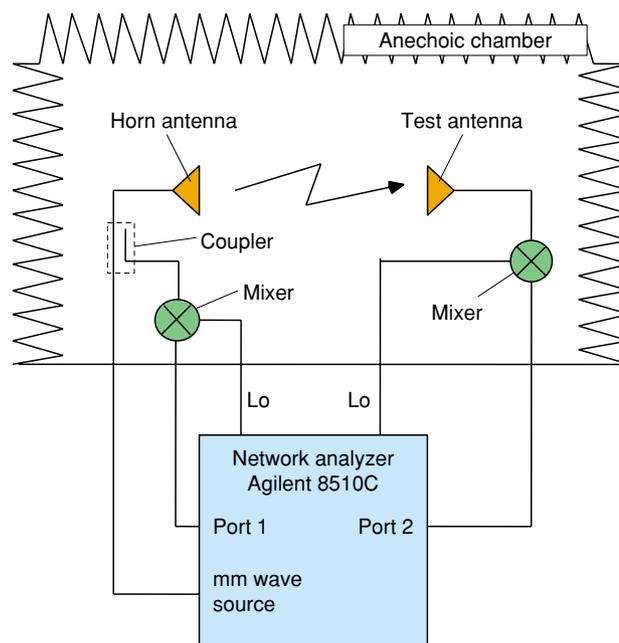

Fig. 12. Antenna pattern measuring system.

tant issue is the effect on measured values of soldering errors and differences in the connecting torque. To eliminate this deviation, we developed a novel antenna-probing fixture based on an RF on-wafer probing system. As a result, we obtained the same measurement accuracy as for MMIC chip measurements for the radiation pattern of miniaturized antennas in the millimeter-wave frequency band. Our millimeter-wave radiation pattern measuring system is shown in **Fig. 12**. The configuration using an RF

probe is shown in **Fig. 13** and a photograph of the system is shown in **Fig. 14**. These on-wafer probes can be directly connected to an antenna terminal formed on the planar substrate. This system can measure the antenna radiation without the need to mount RF connectors on the antenna substrate. This method yields higher accuracy and higher efficiency. This fixture has two probe heads. One probe is used to feed the RF signal to the antenna terminal and the other is used to feed the control signal and DC power to the devices mounted on the antenna substrate.

#### 4.2 MPMAA on Teflon substrate

We manufactured a prototype antenna with a Teflon substrate to confirm the design for the 60-GHz band. We used a microstrip line (MSL) and a via hole to feed the MSA, which acted as the feeding element shown in Fig. 2. Two parasitic layers were arranged so that the size and location of the MSA and parasitic elements, the substrate thickness, and the location of the feeding points yielded the maximum absolute gain as described in the previous section. A photograph of the prototype antenna is shown in **Fig. 15**. The left side shows a side view of the antenna element and the right side shows the feeding line. The fabricated prototype antenna chip size is 10.0 mm × 10.0 mm × 1.1 mm. The E-plane and H-plane radiation patterns are shown in **Fig. 16**. The measured and calculated radiation patterns had fairly similar main lobes.

Next, we discuss the bandwidth of this antenna. The frequency characteristics of the measured maximum gain and the  $S_{11}$  characteristics are shown in **Fig. 17**. The frequency bandwidth for the gain that is 3 dB below the peak gain for this antenna is from 59.3 to 62.6 GHz. Therefore, the bandwidth compared with the center frequency is 5.5%. The  $S_{11}$  frequency characteristics and the gain are in good agreement with the calculated results shown in Fig. 6. Moreover, we can see that the estimated absolute gain is greater than 8.5 dBi because the measured absolute gain of this antenna is greater than 7.4 dBi including the RF probe loss, which is approximately 1.1 dB at 60 GHz. The difference between the calculated and measured gains is approximately 3 dB. Here, we discuss three possible causes for this gain reduction: 1) loss in the microstrip line or coplanar line transition, 2) a discrepancy between the designed and actual values of the bonding film thickness resulting from the manufacturing process, and 3) the fabrication accuracy in the antenna manufacturing process. More specifically, the gain reduction due to the change in bonding

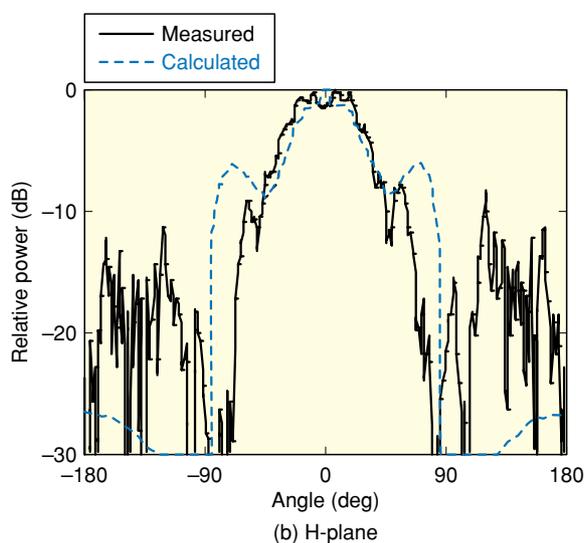

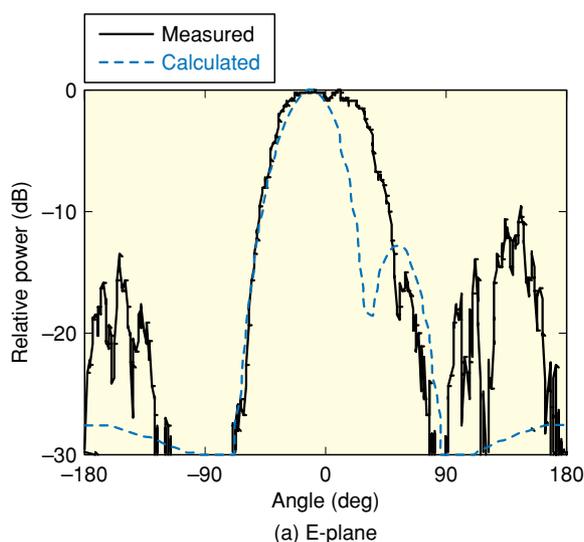

Fig. 16. Measured radiation pattern of MPMAA on Teflon substrate.

film thickness was at least 1 dB, even when the antenna's alignment accuracy at the time of manufacture was approximately 100  $\mu\text{m}$ . One topic for future study is to find a bonding film material that has electrical characteristics similar to the Teflon substrate. Furthermore, it seems that the alignment binding accuracy of the multilayer Teflon substrate needs to be improved to approximately 50  $\mu\text{m}$ .

### 4.3 MPMAA on LTCC substrate

A photograph of the prototype antenna fabricated on an LTCC substrate is shown in Fig. 18. The left side shows a side view of the antenna element and the right side shows the feeding line. The radiation characteristics of the prototype antenna are shown in Fig.

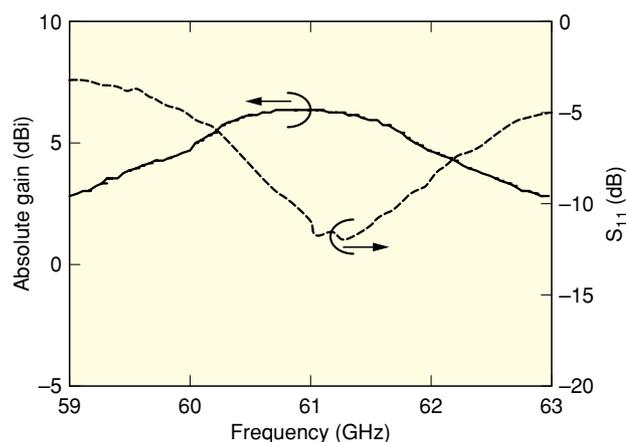

Fig. 17. Absolute gain and  $S_{11}$  of MPMAA on Teflon substrate.

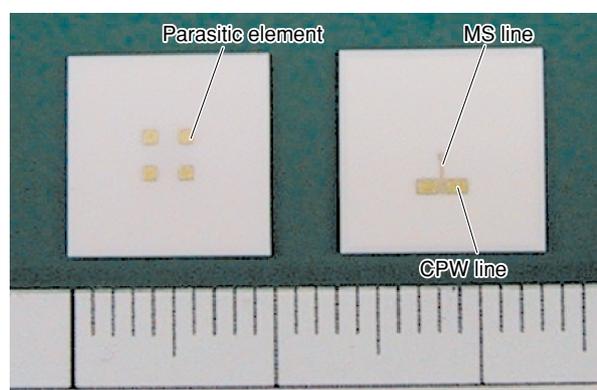

Fig. 18. Photograph of MPMAA fabricated on LTCC substrate.

19. The measured and calculated main lobe characteristics are in good agreement. Furthermore, we clarified that the measured absolute gain of this antenna is 7.17 dBi including the RF probe loss, which is approximately 1.2 dB at 60 GHz. The frequency bandwidth for the gain that is 3 dB below the peak gain for this antenna is from 59.3 to 61.3 GHz. Therefore, the bandwidth compared with the center frequency is 3.3%.

## 5. Conclusion

We described a highly efficient multilayer parasitic microstrip antenna array (MPMAA) constructed on a multilayer substrate for millimeter-wave system-on-package modules. The basic design and performance of the array antenna were described when a Teflon substrate was used. We also described the effects of the substrate and the alignment of parasitic elements

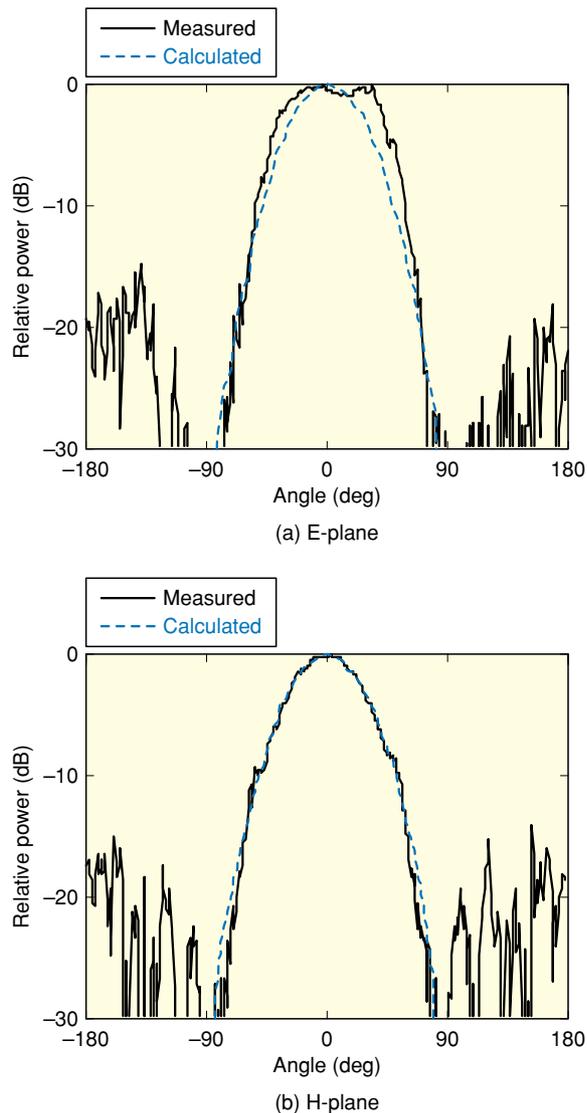

Fig. 19. Measured radiation pattern of MPMAA on LTCC substrate.

on antenna performance. The radiation efficiency and associated antenna gain of the antenna on a Teflon substrate were greater than 91% and 11.1 dBi, respectively. We discussed fabricated 60-GHz-band MPMAAs on both Teflon and LTCC substrates and presented performance measurement results. The MPMAA offers compactness and high efficiency and is suitable for system-on-package modules. Thus, it enables us to make compact and cost-effective millimeter-wave RF modules.
